

# Package ‘mortAAR’

April 10, 2025

**Type** Package

**Title** Analysis of Archaeological Mortality Data

**Version** 1.1.8

**Maintainer** Nils Mueller-Scheessel <nils.mueller-scheessel@ufg.uni-kiel.de>

**Description** A collection of functions for the analysis of archaeological mortality

data (on the topic see e.g. Chamberlain 2006

[https://books.google.de/books?id=nG5Fo0\\_becAC&lpg=PA27&ots=LG0b\\_xrx60&dq=life%20table%20archaeology&pg=PA27#v=onepage&q&f=false](https://books.google.de/books?id=nG5Fo0_becAC&lpg=PA27&ots=LG0b_xrx60&dq=life%20table%20archaeology&pg=PA27#v=onepage&q&f=false)).

It takes demographic data in different formats and displays the result in a standard life table as well as plots the relevant indices (percentage of deaths, survivorship, probability of death, life expectancy, percentage of population). It also checks for possible biases in the age structure and applies corrections to life tables.

**Date** 2025-04-10

**License** GPL-3 | file LICENSE

**Encoding** UTF-8

**LazyData** true

**Imports** magrittr (>= 1.5), Rdpack (>= 0.4-20), reshape2 (>= 1.4.2), methods (>= 3.3.3), tibble (>= 3.0.3), rlang (>= 1.1.1), flexsurv (>= 2.2.2), stats (>= 4.3.1)

**RoxxygenNote** 7.2.3

**Suggests** testthat, knitr, rmarkdown, tidyverse, dplyr, ggplot2

**Depends** R (>= 3.5.0)

**RdMacros** Rdpack

**VignetteBuilder** knitr

**Config/testthat/edition** 3

aiterhofen\_oedmuehlen *aiterhofen\_oedmuehlen: Life table example*

---

## Description

A life table from *Kokkotidis/Richter 1991*, 228.

## Format

A data frame with 13 rows and 11 variables.

- **Alter** (age)
- **a** (added to the original dataset)
- **Dx**
- **Sx**
- **qx**
- **lx**
- **dx**
- **Lx**
- **Tx**
- **ex**
- **rel.Bevx**

For further information about the values see the documentation of [life.table](#).

## Details

The life table is compiled from the Linear pottery burial site Aiterhofen Ödmühle (Lower Bavaria). More information can be found in *Baum 1990*.

## References

gallery\_graves

*gallery\_graves: Life table example***Description**

A dataset from *Czarnetzki 1966*.

**Format**

A data frame with 128 rows and 4 variables.

- **indnr:** ID of the individual represented by a skull.
- **sex:** sex determination, w -> female, m -> male.
- **age:** age class.
- **site:** collective grave.

**Details**

Skulls from four different collective graves. This dataset is not well prepared and needs some adjustment.

**References**

halley.band

*Halley band of the mortality profile of a skeletal population***Description**

In a series of papers, M. A. Luy and U. Wittwer-Backofen (2005; 2008) proposed a method they called 'Halley band' as alternative for other methods of sampling from an skeletal population. It basically involves sampling n times from the age-estimation of each individual and then only taking the 2.5th and 97.5th percentile into account. The space between, they dubbed 'Halley band' but pointed out that it is not to be confused with confidence intervals.

**Usage**

```
halley.band(x, n = 1000, uncert = 0.95, agebeg, ageend, agerange = "excluded")
```

## Arguments

x	a data.frame with individuals and age estimations.
n	number of runs, default: 1000.
uncert	level of uncertainty, default: 0.95.
agebeg	numeric. Starting age of the respective individual.
ageend	numeric. Closing age of the respective individual.
agerange	character. Determination if the closing age leaves a gap to the following age category. If yes (= "excluded"), "1" is added to avoid gaps, default: "excluded".

## Value

One data.frame with the following items:

- **age**: age in years.
- **lower\_dx**: Lower boundary of uncertainty for dx.
- **upper\_dx**: Upper boundary of uncertainty for dx.
- **lower\_qx**: Lower boundary of uncertainty for qx.
- **upper\_qx**: Upper boundary of uncertainty for qx.
- **lower\_lx**: Lower boundary of uncertainty for lx.
- **upper\_lx**: Upper boundary of uncertainty for lx.

## Examples

```
# create simulated population with artifical coarsening first
pop_sim <- pop.sim.gomp(n = 1000)
sim_ranges <- random.cat()

# apply random age categories to simulated ages
sim_appl <- random.cat.apply(pop_sim$result, age = "age",
age_ranges = sim_ranges, from = "from", to = "to")

# create halley bands
demo <- halley.band(sim_appl, n = 1000, uncert = 0.95, agebeg = "from",
ageend = "to", agerange = "excluded")

# plot band with ggplot
library(ggplot2)
ggplot(demo) + geom_ribbon(aes(x = age, ymin = lower_dx, ymax = upper_dx),
```

```
linetype = 0, fill = "grey")
ggplot(demo) + geom_ribbon(aes(x = age, ymin = lower_lx, ymax = upper_lx),
linetype = 0, fill = "grey")
ggplot(demo) + geom_ribbon(aes(x = age, ymin = lower_qx, ymax = upper_qx),
linetype = 0, fill = "grey")
```

**life.table***Calculates a life table***Description**

`life.table` calculates **life table(s)**. The algorithm is optimised for deceased populations encountered in archaeological research. See *Chamberlain 2006*, 27ff., *Herrmann et. al 1990*, 303ff., *Kokkotidis/Richter 1991*, *Keyfitz et al. 2005* for selected literature.

The function takes an individual data.frame or a list of data.frames and returns an object of class `mortaar_life_table` or `mortaar_life_table_list`, for which specialised summary, print and plot functions exist.

**Usage**

```
life.table(neclist, agecor = TRUE, agecorfac = c(), option_spline = NULL)
```

**Arguments**

<code>neclist</code>	single data.frame or list of data.frames with the columns ' <code>x</code> ', ' <code>a</code> ', ' <code>Dx</code> '.
	<ul style="list-style-type: none"> <li>• <code>x</code>: age interval identifier, optional. - Otherwise determined from <code>a</code>.</li> <li>• <code>a</code>: years within <code>x</code>.</li> <li>• <b>Dx</b>: number of deaths within <code>x</code>.</li> </ul>
<code>agecor</code>	logical, optional. If set TRUE, the average number of years lived within a given age class of individuals having died in this class can be adjusted via <code>agecorfac</code> . If set FALSE, it is assumed that they died in the middle of this class. Due to the higher mortality rates of infants, this assumption is certainly inaccurate for individuals $\leq 5$ years. Default setup is: TRUE.
<code>agecorfac</code>	numeric vector, optional. Only applies if <code>agecor == TRUE</code> . Given values replace the standard values from the first age interval onward. Default setup is 1/3 for every age class $\leq 5$ life years, and 1/2 for the others.
<code>option_spline</code>	integer, optional. If $> 0$ , values for adults will be interpolated by a monotonic cubic spline. Usual options will be '10' or '20' which will interpolate the values for individuals of an age of 20 or older by 10- or 20- year cumulated values. To be used carefully, as diagnostic features of the life table might be smoothed and essentially removed. Only available when the methods 'Standard' or 'Equal5' in <code>prep.life.table</code> have been chosen.

## Value

An object of class mortaar\_life\_table or mortaar\_life\_table\_list. Each mortaar\_life\_table contains the following variables:

- **x**: age interval.
- **a**: years within x.
- **Ax**: average number of years lived by an individual that died within a specific age class x :  

$$A_x = a_x * agecorfac_x$$
- **Dx**: number of deaths within x.
- **dx**: proportion of deaths within x (percent) :  

$$d_x = \frac{D_x}{\sum_{i=1}^n D_i} * 100$$
- **Ix**: survivorship within x (percent) :  

$$l_{x+1} = l_x - d_x \text{ with } l_0 = 100$$
- **qx**: probability of death within x (percent) :  

$$q_x = \frac{d_x}{l_x} * 100$$
- **Lx**: number of years lived within x by those that died within x and those that reached the next age class :  

$$L_x = (a_x * l_x) - ((a_x - A_x) * d_x)$$
- **Tx**: sum of years lived within current and remaining x :  

$$T_{x+1} = T_x - L_x \text{ with } T_0 = \sum_{i=1}^n L_i$$
- **ex**: average years of life remaining (average life expectancy at mean(x)) :  

$$e_x = \frac{T_x}{l_x}$$
- **rel\_pox**: percentage of L(x) of the sum of L(x) :  

$$relopox_x = \frac{L_x}{\sum_{i=1}^n L_i} * 100$$

## Examples

```
# Create a mortaar_life_table from a prepared dataset.
schleswig_1 <- life.table(schleswig_ma[c("a", "Dx")])
print(schleswig_1)
plot(schleswig_1, display = "lx")
```

```

# Create a mortaar_life_table_list from two datasets.
odagsen <- life.table(list(
  "corpus mandibulae" = odagsen_cm[c("a", "Dx")],
  "margo orbitalis" = odagsen_mo[c("a", "Dx")]
))
print(odagsen)
plot(odagsen, display = "ex")

# Prepare a real world dataset and create a mortaar_life_table.
library(magrittr)
magdalenenberg %>%
  replace(. == "60-x", "60-70") %>%
  tidyrr::separate(a, c("from", "to")) %>%
  dplyr::mutate(from = as.numeric(from), to = as.numeric(to)) %>%
  prep.life.table(
    dec = "Dx",
    agebeg = "from",
    ageend = "to",
    method = "Standard",
    agerange = "excluded"
  ) %>%
  life.table()

```

**lt.correction***Calculates a corrected life table from a mortAAR life table***Description**

It is generally assumed that most skeletal populations lack the youngest age group. Life tables resulting from such populations will necessarily be misleading as they lead to believe that the mortality of younger children was lower than it actually was and that life expectancy was higher. For correcting these missing individuals, *Bocquet-Appel and Masset* (1977; see also *Herrmann et al.* 1990, 307) conceived of several calculations based on regression analyses of modern comparable mortality data. However, the applicability of these indices to archaeological data is highly debated and does not necessarily lead to reliable results. Therefore, the correction needs to be weighted carefully and ideally only after the representativity of the base data has been checked with function *lt.representativity*.

**Usage**

```
lt.correction(life_table, agecor = TRUE, agecorfac = c(), option_spline = NULL)
```

**Arguments**

- life\_table** an object of class *mortaar\_life\_table*.
- agecor** logical, optional. Passed to [life.table](#).
- agecorfac** numeric vector, optional. Passed to [life.table](#).
- option\_spline** integer, optional. Passed to [life.table](#).

## Details

For the parameters see the documentation of [life.table](#).

## Value

a list containing a data.frame with indices e0, 1q0 and 5q0 as well as mortality rate m and growth rate r according to Bocquet-Appel and Masset showing the computed exact value as well as ranges and an object of class mortaar\_life\_table with the corrected values.

- **e0**: Corrected life expectancy.
- **1q0**: Mortality of age group 0–1.
- **5q0**: Mortality of age group 0–5.

## References

## Examples

```
# Calculate a corrected life table from real life dataset.
schleswig <- life.table(schleswig_ma[c("a", "Dx")])
lt.correction(schleswig)
```

**lt.indices**

*Generates indices from a mortAAR life table for use in other functions*

## Description

This function bundles a number of indices and vectors from a mortAAR life table which are needed by other functions in mortAAR. The results are only meaningful if 5-year-categories have been chosen to construct the life table.

## Usage

```
lt.indices(life_table)
```

## Arguments

life_table	an object of class mortaar_life_table.
------------	--

**Value**

A list with the following indices and vectors:

- **child\_i**: ratio of individuals aged 5–9 to those aged 10–14 according to *Masset and Bocquet 1977*.
- **juvenile\_i**: ratio of individuals aged 5–14 to adults according to *Masset and Bocquet 1977*.
- **P(5-19)**: ratio of individuals aged 5–19 to those aged 5 or above according to *Bocquet-Appel 2002*.
- **D30\_D5**: ratio of individuals aged 30 and above to those aged 5 or above according to *Buikstra et al. 1986*.
- **D0\_14\_D**: proportion of individuals aged 0–14 according to *McFadden & Oxenham 2018a* if infants are represented well.
- **D15\_49\_D15plus**: proportion of individuals aged 15–49 according to *Taylor & Oxenham 2024*.
- **e0**: life expectancy at age 0.

**Examples**

```
schleswig <- life.table(schleswig_ma[c("a", "Dx")])
lt.indices(schleswig)
```

<i>lt.population_size</i>	<i>Calculates population size from a mortAAR life table or numeric values</i>
---------------------------	---

**Description**

The estimation of the population size for a given cemetery is only possible if a stationary population is assumed. In this case, the number of deaths is simply multiplied with the life expectancy at birth and divided by the time span in years the cemetery was in use. Additionally, it is assumed that an unknown number of individuals is not represented in the cemetery and, therefore, the resulting number is multiplied by an arbitrary value k (*Herrmann et al. 1990*, 311f.).

## Usage

```
lt.population_size(x, e0, k = 1.1, t)
```

## Arguments

x	either an object of class mortaar_life_table or mortaar_life_table_list or an arbitrary numeric value representing the number of deaths.
e0	numeric. life expectancy at birth in years (if x is of class mortaar_life_table then e0 can be derived directly from the life table's ex column).
k	numeric. Arbitrary number to cater for individuals not represented in the number of deaths. Default: 1.1.
t	numeric. Time span of usage of cemetery in years.

## Value

A data.frame with the following items:

- **D**: Number of deaths.
- **e0**: Life expectancy at birth in years.
- **k**: Correction factor.
- **t**: Time span of usage of cemetery in years.
- **P**: Population size calculated by the formula  $P = D * e0 * k / t$

## References

Herrmann B, Grupe G, Hummel S, Piepenbrink H, Schutkowski H (1990). *Praehistorische Anthropolologie: Leitfaden der Feld- und Labormethoden*. Springer, Berlin.

## Examples

```
schleswig <- life.table(schleswig_ma[c("a", "Dx")])
lt.population_size(schleswig, t = 100)

odagsen <- life.table(list(
  "corpus mandibulae" = odagsen_cm[c("a", "Dx")],
  "margo orbitalis" = odagsen_mo[c("a", "Dx")]
))
lt.population_size(odagsen, e0 = 30, t = 100)

lt.population_size(x = 111, e0 = 32.2, k = 1.2, t = 100)
```

---

lt.representativity	<i>Checks the representativity of the non-adult age groups in a mortAAR life table</i>
---------------------	--

---

## Description

Weiss 1973, 46f. and Bocquet-Appel and Masset 1977 (see also Herrmann et al. 1990, 306f.) have devised indices which check if the non-adult age groups are represented in proportions as can be expected from modern comparable data. Whether this is really applicable to archaeological datasets is a matter of debate.

Quite recently, Taylor and Oxenham 2024 added a comparison of Total fertility rates (TRF) according to different formulas which depend either on subadults or adults.

Weiss chose the mortality ( $qx$ ) as deciding factor and claimed that (1) the probability of death of the age group 10–15 (5q10) should be lower than that of the group 15–20 (5q15) and that (2) the latter in turn should be lower than that of age group 0–5 (5q0).

In contrast, Bocquet-Appel and Masset took the raw number of dead ( $Dx$ ) and asserted that (1) the ratio of those having died between 5 and 10 (5D5) to those having died between 10 and 15 (5D15) should be equal or larger than 2 and that (2) the ratio of those having died between 5 and 15 (10D5) and all adults ( $\geq 20$ ) should be 0.1 or larger.

The formulas Taylor and Oxenham used either weigh all individuals aged 0–14 against all individuals or all individuals aged 15–49 against all individuals aged 15+. The formulas differ from the original ones published by McFadden and Oxenham 2018 and Taylor et al. 2023 because the data basis is slightly different. If the results of the formulas deviate by more than 0.692 (the standard error of estimate, SEE), there is a problem with the age structure.

Due to the specific nature of the indices, they only give meaningful results if 5-year-age categories have been chosen for the non-adults.

## Usage

```
lt.representativity(life_table)
```

## Arguments

life\_table      an object of class mortaar\_life\_table.

## Value

data.frame showing the indices and explaining their interpretation.

## Examples

```
schleswig <- life.table(schleswig_ma[c("a", "Dx")])
lt.representativity(schleswig)
```

<code>lt.reproduction</code>	<i>Calculates reproduction indices from a mortAAR life table</i>
------------------------------	--

## Description

For population studies it is of vital importance to estimate growth or decline of a population. For archaeological datasets this is rarely attempted, probably because the data quality seems to scanty. Nevertheless, the calculation of such measures seems worth the try, at least it should give an impression if the resulting values are unrealistic high or low.

## Usage

```
lt.reproduction(
  life_table,
  fertility_rate = "BA_log",
  growth_rate = "fertility",
  gen_len = 20
)
```

## Arguments

<code>life_table</code>	an object of class <code>mortaar_life_table</code> .
<code>fertility_rate</code>	string or numeric. Either fertility rate according to <i>McFadden &amp; Oxenham 2018a</i> if infants are represented well or <i>Taylor et al.</i> or fertility rate according to data by <i>McFadden &amp; Oxenham 2018a</i> for P(5-19) index after <i>Bocquet-Appel 2002</i> . Options: 'McFO' (McFadden/Oxenham), 'TOMC' (Taylor et al.), 'BA_linear' (linear fit), 'BA_power' (power fit) or 'BA_log' (logistic fit). Default: BA_log'. Additionally, the user can specify an arbitrary number in lieu of the fertility rate.
<code>growth_rate</code>	string or numeric. Either derived directly from the fertility calculations or from regression analysis by either <i>McFadden &amp; Oxenham 2018b</i> ( $10.06 * D0 - 14/D - 1.61$ ) or <i>Bocquet-Appel and Masset</i> ( $(1.484 * (\log_{10}(200 * d5 - 14/d20 * d60/d20)) * 0.03 - 1.485)$ ). Options: 'fertility', 'MBA', 'McFO'. Additionally, the user can specify an arbitrary number in lieu of the growth rate.
<code>gen_len</code>	numeric. Length of generation for determining the rate of doubling the population. Default: 20.

## Details

There are different approaches to calculate reproduction rates (e. g. *Henneberg 1978*). We largely follow the methodology by *Hassan 1981*. Typically, a Total fertility rate (TFR) of 6-8 is assumed for prehistoric populations (*Ascadi/Nemeskeri 1970; Henneberg 1978; Hassan 1981*). Recently, *McFadden and Oxenham 2018a* have published a formula to estimate the Total fertility rate from archaeological data, provided that infants are represented fully in the archaeological record.

Unfortunately, this will not be the case for most archaeological datasets. Therefore, we used the data published by McFadden and Oxenham to apply it to the P(5-19)-index after *Bocquet-Appel 2002*. We approximated the ratio by three different methods of fitting (linear, logistic, power) and recommend logistic fitting, but the others are available as well.

We have also added the option to use the formula by *Taylor et al. 2023* that uses the ratio of adults aged 15–49 in relation to those aged 15 or older.

The Gross reproduction rate (GRR) is calculated by multiplying the TFR with the ratio of female newborns, assumed to be a constant of 48.8 of all children (*Hassan 1981*, 136). The Net reproduction rate is arrived at by summing the product of the GRR, the age specific fertility rate as defined by *Hassan* (1981, 137 tab. 8.7) and the age specific survival taken from the life table and dividing the result by 10000.

The Rate of natural increase or Intrinsic growth rate  $r$  (growth in per cent per year) can be computed from the fertility following *Hassan* (1981, 140). Alternative ways to calculate the intrinsic growth rate derive from *Bocquet-Appel and Masset* (1977) and recently from *McFadden and Oxenham 2018b*. The latter present a regression analysis based on the index D0–15/D also used for fertility calculations (see above) in connections with modern data.

Whatever is chosen as base for the growth rate calculations is used for computing the doubling time in years, assuming exponential steady growth.

Also calculated is the mortality rate  $m$  after *Bocquet-Appel and Masset* (1977) in per cent of a given population. Furthermore, the ratio of dependent individuals is reported that is usually (but probably erroneously for archaic societies (*Grupe et al. 2015*, 423) assumed to apply to those aged below 15 or 60 and above.

Finally, *Buikstra et al. 1986* have made the interesting observation that the relation of those individuals aged 30 years and above to those aged 5 years and above is very closely related to the birth rate and also closely (but less significantly) related to the death rate. Therefore, these indices are calculated as well.

## Value

A data.frame with basic reproduction indices:

- **m**: Mortality rate (= natality rate n).

$$0.127 * d5 - 14/d20 + 0.016$$

- **dep**: Dependency ratio.

$$DR = (sum(D0 - 14) + sum(D60+))/sum(D15 - 59)$$

- **TFR**: Total fertility rate.

- **GRR**: Gross reproduction rate.

$$GRR = TFR * 0.488$$

- **NRR**: Net reproduction rate.

$$NRR = sum(GRR * agespecificfertility * agespecificsurvival / 10000)$$

- **r:** Intrinsic growth rate in per cent per year.
- **Dt:** Doubling time in years.  

$$Dt = 100 * \ln(2)/r$$
- **D30\_D5:** Ratio D30+/D5+ after Buikstra et al.
- **BR:** Birth rate from ratio D30+/D5+.  

$$BR = -11.493 * D30_D5 + 12.712$$
- **DR:** Death rate from ratio D30+/D5+.  

$$DR = -5.287 * D30_D5 + 6.179$$

## Examples

```

schleswig <- life.table(schleswig_ma[c("a", "Dx")])
lt.reproduction(schleswig)

odagsen <- life.table(list(
  "corpus mandibulae" = odagsen_cm[c("a", "Dx")],
  "margo orbitalis" = odagsen_mo[c("a", "Dx")]
))
lt.reproduction(odagsen)

```

---

lt.sexrelation	<i>Calculate masculinity index and maternal mortality from a mortAAR life table list</i>
----------------	--

---

## Description

The proportional relation between adult males and females (= Masculinity index) is interesting for a number of reasons: (1) it can point to basic problems in the datasets in that, say, one sex is grossly over- or underrepresented (*Herrmann et al. 1990*, 310). (2) it may hint towards cultural reasons like sex- specific mobility.

Maternal mortality is a basic indicator for the health system of a given population. Maternal mortality is defined as dying during pregnancy or within the first 42 days after birth due to complications. Recently, *McFadden and colleagues 2020* have provided an updated formula to calculate it from archaeological data.

## Usage

```
lt.sexrelation(females, males)
```

## Arguments

- |         |   |
|---------|---|
| females | an object of class mortaar_life_table for females |
| males   | an object of class mortaar_life_table for males   |

## Details

The Masculinity index (MI) is defined for juvenile and older individuals. Note that with a higher mortality rate of adult females, an MI < 100 does not necessarily speak for an unbalanced MI in life.

Maternal mortality is calculated according to the formula provided by *McFadden & Oxenham 2019* in the updated version of *McFadden et al. 2020*. McFadden and Oxenham show that with modern data a very high correlation is achieved by only comparing the absolute numbers of the age group 20 to 24. This has the additional advantage that for this age group anthropological aging methods are reasonable exact.

## Value

Output of masculinity index and maternal mortality.

- **Masculinity index.**

$$MI = D \geq 15male / D \geq 15female$$

- **Maternal mortality.**

$$333.33 * (D20 - 24female / D20 - 24male) * MI - 76.07$$

## Examples

```
# Calculate Masculinity index and maternal mortality from Nitra
# dataset.
nitra_prep <- prep.life.table(nitra, group="sex", agebeg = "age_start", ageend = "age_end")
nitra_life <- life.table(nitra_prep)
lt.sexrelation(nitra_life$f, nitra_life$m)
```

magdalenenberg

magdalenenberg: Life table example

## Description

A data set from *zaeuner\_wahl\_magdalenenberg\_2013*.

## Format

A data frame with 13 rows and 2 variables.

- **a:** age range.
- **Dx:** number of deceased.

## Details

Anthropological data from a large burial mound of the Early Iron Age in southwestern Germany. It is already pooled for constructing a life table.

## References

- Zaeuner S, Wahl J (2013). “Zur demographischen Struktur der Bestattungen im späthallstattzeitlichen Grabhügel vom Magdalenenberg.” *Fundberichte aus Baden-Württemberg*, **33**, 133–145.

`mortaar_life_table`      *mortaar\_life\_table and mortaar\_life\_table\_list*

## Description

The **`mortaar_life_table`** is the central data structure of the `mortaAR` package. It's a data.frame with set of custom methods and variables. Please see `mortaAR::life.table` for a description of the variables. Further available variables are ignored.

If an object is of class data.frame or tibble (tbl & tbl\_df), it can be converted to an object of class `mortaar_life_table`. The only requirement is that it contains at least the essential columns **a** and **Dx**. The `as` function adds the string "mortaar\_life\_table" to the classes vector.

The **`mortaar_life_table_list`** is a list of `mortaar_life_table`s. It can contain the additional attribute group that stores a string with the name of the grouping variable relevant for the separation of the different `mortaar_life_table`s in the list. The group variable is only relevant for plot and print aesthetics.

## Usage

```
as.mortaar_life_table_list(x, ...)
as.mortaar_life_table(x, ...)
```

## Arguments

x	an object
...	further arguments passed to or from other methods

## Examples

```
# a mortaar_life_table can be put together manually:
as.mortaar_life_table(data.frame(a = c(20, 20, 20), Dx = c(10, 15, 20)))

# a mortaar_life_table_list can be constructed from multiple mortaar_life_tables
schleswig <- as.mortaar_life_table_list(
  list(
    "schleswig data 1" = life.table(schleswig_ma[c("a", "Dx")]),
    "schleswig data 2" = life.table(schleswig_ma[c("a", "Dx")])
  )
)

# you can add new mortaar_life_tables to plot them with the others
schleswig$`schleswig data 3` <- life.table(schleswig_ma[c("a", "Dx")])
schleswig[["schleswig data 4"]] <- life.table(schleswig_ma[c("a", "Dx")])

# and you can create arbitrary subsets of mortaar_life_table_lists
schleswig_data_3 <- schleswig$`schleswig data 3`
schleswig_data_1_3_4 <- schleswig[c(1,3,4)]
```

---

muensingen

*muensingen: Life table example*

---

## Description

A data set from *moghaddam\_et\_al\_muensingen\_2016*.

## Format

A data frame with 71 rows and 4 variables.

- **age:** age range of the individual.
- **sex:** sex of the individual.
- **latene\_phase:** archaeological phasing.
- **grave\_goods:** did the grave contain grave goods?

## Details

Anthropological data from one of the largest Latene burial grounds of Central Europe. Besides age and sex of each individual, it comprises the archaeological phasing (A, B or C) and the information if the respective burial contained grave goods (yes or no).

---

nitra

*nitra: Life table example*

---

## Description

The Early Neolithic cemetery of Nitra is one of the best published data sets of the *Linearbandkeramik* (LBK). The individuals were analysed by J. Jelínek (published in *Pavúk 1972*) and many decades later also bei L. Fibiger (*Bickle/Whittle 2013*, 139ff. Tab. 4.15) and in more detail by Z. Tvrđý 2016. We follow here the determinations by L. Fibiger.

## Format

A data frame with 4 variables and 75 observations

- **no:** individual
- **sex:** sex determination if available
- **age\_start:** start of the ageing interval
- **age\_end:** end of the ageing interval (inclusive)

## References

odagsen\_cm

*odagsen\_corpus.mandibulae: Life table example*

## Description

A life table from *Grupe/Herrmann 1986, 51.*

## Format

A data frame with 11 rows and 9 variables.

- **age.group:** inf.I, inf.II -> Infans I, II juv -> juvenil; fa, ma, sa -> früh-, mittel-, spätadult; fm, mm, sm -> früh-, mittel-, spätmatur; s -> senil
- **x**
- **a**
- **Dx**
- **dx**
- **lx**
- **qx**
- **Lx**
- **ex**

In contrast to the general convention **Lx** represents the remaining survivors of each age interval ("Zahl der Lebenden bezogen auf die theoretische Ausgangspopulation zwischen zwei aufeinanderfolgenden Intervallen"). For further information about the values see the documentation of [life.table](#).

## Details

The life table is compiled from the mandibulae of the late neolithic collective burial #' from Odagsen, Einbeck district Northeim (3.250 - 2.950 cal BC). The calculated values show minor adjustments in comparison to the published original data in *Grupe/Herrmann 1986*.

plot

*Plot a mortaar\_life\_table or a mortaar\_life\_table\_list*

## Description

Plot a mortaar\_life\_table or a mortaar\_life\_table\_list. There are several different kinds of plots to explore the different variables. The parameter display allows to select the variables of interest.

## Arguments

- |               |   |
|---------------|---|
| x             | a mortaar_life_table or a mortaar_life_table_list.  |
| display       | a character vector. Displays the calculated variables as plots. These must include some of the alternatives dx for the proportion of deaths, qx for the probability of death, lx for the survivorship, ex for the life expectancy and rel_pox for the population age structure. |
| line_vis      | optional string. Differentiate groups either by "linetype" or by "color". Default to "linetype".  |
| prefer.ggpolt | should ggplot be preferred, if available. Default to TRUE.  |
| ...           | further arguments passed to or from other methods.  |

## Examples

```
# Create a mortaar_life_table from a prepared dataset.
schleswig_1 <- life.table(schleswig_ma[c("a", "Dx")])
plot(schleswig_1)
plot(schleswig_1, display = "qx")

# Create a mortaar_life_table_list from two datasets.
```

```

odagsen <- life.table(list(
  "corpus mandibulae" = odagsen_cm[c("a", "Dx")],
  "margo orbitalis" = odagsen_mo[c("a", "Dx")]
))
plot(odagsen)
plot(odagsen, display = "lx", line_vis="color")

```

pop.sim.gomp

*Simulation of a population of adults with Gompertz distribution*

## Description

In many instances, it is useful to calculate with a population with known parameters. To generate a population with realistic characteristics is less obvious than it seems. We operate here with the Gompertz distribution which provides a reasonable approximation of human mortality for **adult** mortality, that is for the ages  $\geq 15$  years. The user has to specify either the parameter **b** or the modal age **M**. The modal age **M** is particular useful as it provides an intuitive understanding of the resulting age distribution. In both instances, the second parameter **a** is generated by the regression formula found by *Sasaki and Kondo 2016*. If neither is given, a population with random parameters realistic for pre-modern times is generated.

## Usage

```
pop.sim.gomp(n, b = NULL, M = NULL, start_age = 15, max_age = 100)
```

## Arguments

<b>n</b>	number of individuals to be simulated.
<b>b</b>	numeric, optional. Gompertz parameter controlling the level of mortality.
<b>M</b>	numeric, optional. Modal age <b>M</b> .
<b>start_age</b>	numeric. Start age, default: 15 years.
<b>max_age</b>	numeric. Maximal age, to avoid unlikely centenaries, default: 100 years.

## Value

A list of two data.frames with the following items:

First data.frame

- **N**: Number of individuals.
- **b**: Gompertz parameter controlling mortality.
- **M**: Modal age.
- **a**: Gompertz parameter controlling hazard of the youngest age group.

Second data.frame

- **ind**: ID of individuals.
- **age**: Simulated absolute age.

## References

Sasaki T, Kondo O (2016). “An informative prior probability distribution of the gompertz parameters for bayesian approaches in paleodemography.” *American Journal of Physical Anthropology*, **159**(3), 523–533. doi:[10.1002/ajpa.22891](https://doi.org/10.1002/ajpa.22891).

## Examples

```
pop_sim <- pop.sim.gomp(n = 10000, M = 35)
pop_sim <- pop.sim.gomp(n = 10000, b = 0.03)
pop_sim <- pop.sim.gomp(n = 10000)
```

**prep.life.table**      *Creates the input for the function life.table*

## Description

Prepares the input for `life.table()`. An individual based approach is supported as well as already pooled data (e. g. from an already existing life table). In the latter case, the user has to specify a numerical variable (**dec**) which defines the count for each age class. If no life table exists, this function will process a dataframe including the age ranges of individuals or groups of individuals to discrete the age classes. The age range is spread to single years. **agebeg** has to be specified for the beginning of an age range, as well as **ageend** for the end of an age range. If a data-set with year-known individuals is used, **ageend** can be omitted but then the parameter **agerange** has to left on its default value (`included`). The **method** defines in which way the single years between the different age classes are split. If the data set comprises a grouping variable (e.g., sex), this can be specified with **group**.

## Usage

```
prep.life.table(
  x,
  dec = NA,
  agebeg,
  ageend = NA,
  group = NA,
  method = "Standard",
  agerange = "included"
)
```

## Arguments

<b>x</b>	single dataframe containing sex age and quantity of deceased (individuals or group of individuals).
<b>dec</b>	column name (as character) of the count of deceased, optional.
<b>agebeg</b>	column name (as character) for the beginning of an age range.
<b>ageend</b>	column name (as character) for the end of an age range, optional.

group	column name (as character) of the grouping field (e.g., sex), optional. Default setup is: NA.
method	character string, optional. Default options is Standard, which will create age classes beginning with 1 year, up to 4 years, followed by steps of 5 years (1,4,5,5,...) until the maximum age is reached. Equal5 will create age classes with an even distribution, stepped by 5 years (5,5,...) until the maximum age is reached. If method is a single numeric, this number will be repeated until the maximum age is reached. Thereby, it is possible to create a year-wise life table.
agerange	character string, optional. Default setup is: included. If the age ranges from "20 to 40" and "40 to 60", excluded will exclude the year 40 from "20 to 40", to prevent overlapping age classes. included is for age ranges like "20 to 39" where the year 39 is meant to be counted.

## Value

A list of input parameter needed for the function `life.table`.

- **x** or **Age**: age interval.
- **a**: years within x.
- **Dx**: number of deaths within x.

## Examples

```
# Separate age ranges in your data set.
df <- dplyr::mutate(
  tidyverse::separate(
    replace(
      magdalenenberg,
      magdalenenberg=="60-x", "60-69"
    ),
    a,
    c("from", "to")
  ),
  from = as.numeric(from),
  to = as.numeric(to)
)

# Apply prep.life.table to a data set containing the age ranges.
magda_prep <- prep.life.table(
  df,
  dec = "Dx",
  agebeg = "from",
  ageend = "to",
  method = "Equal5",
  agerange = "included"
)

# Create a life.table.
life.table(magda_prep)
```

<code>print</code>	<i>Encode and print a mortaar_life_table or a mortaar_life_table_list</i>
--------------------	---

## Description

Format for pretty printing.

## Arguments

<code>x</code>	a mortaar_life_table or a mortaar_life_table_list.
<code>class_of_deceased</code>	optional string, specify the class of deceased (male, female, phase, ...).
<code>...</code>	further arguments passed to or from other methods.

## Value

A string representation of the mortaar\_life\_table or the mortaar\_life\_table\_list. For format.mortaar\_life\_table\_list each mortaar\_life\_table is formatted by itself and strung together. The names of the elements are used to specify the name in the returned header of the printout.

## Examples

```
# Create a mortaar_life_table from a prepared dataset.
schleswig_1 <- life.table(schleswig_ma[c("a", "Dx")])
print(schleswig_1)

# Create a mortaar_life_table_list from two datasets.
odagsen <- life.table(list(
  "corpus mandibulae" = odagsen_cm[c("a", "Dx")],
  "margo orbitalis" = odagsen_mo[c("a", "Dx")]
))
print(odagsen)
```

<code>random.cat</code>	<i>Generation of random age ranges</i>
-------------------------	--

## Description

Helper function that generates random age categories of absolute ages. It is mainly used together with the functions `pop.sim.gomp` and `random.cat.apply`. It will run until the number of categories are reached *and* there are no gaps in the sequence left.

Helper function that applies random age categories to "known" absolute ages. It is mainly used together with the functions `pop.sim.gomp` and `random.cat`.

## Usage

```
random.cat(n_cat = 20, min_age = 15, max_cat_low = 60, max_age = 74)

random.cat.apply(x, age, age_ranges, from, to)
```

## Arguments

<code>n_cat</code>	numeric. Number of categories, default: 20.
<code>min_age</code>	numeric. Minimum age, default: 15.
<code>max_cat_low</code>	numeric. Lower boundary of highest age category, default: 60.
<code>max_age</code>	numeric. Maximum age, default: 74.
<code>x</code>	a data.frame with individual absolute ages.
<code>age</code>	the column containing the individual absolute ages.
<code>age_ranges</code>	a data.frame with age ranges.
<code>from</code>	numeric. Column name for the begin of an age range.
<code>to</code>	numeric. Column name for the end of an age range.

## Value

One data.frame with the following items:

- **from**: Lower boundary of age category.
- **to**: Upper boundary of age category.

The original data.frame `x` with two additional columns:

- **from**: Lower boundary of age category.
- **to**: Upper boundary of age category.

## Examples

```
sim_ranges <- random.cat()

# Simulate population and age ranges first
pop_sim <- pop.sim.gomp(n = 10000)
sim_ranges <- random.cat()

# apply random age categories to simulated ages
sim_appl <- random.cat.apply(pop_sim$result, age = "age",
age_ranges = sim_ranges, from = "from", to = "to")
```

---

schleswig\_ma

*schleswig\_ma: Life table example*

---

## Description

A life table from *Herrmann et. al 1990, 305.*

## Format

A data frame with 11 rows and 9 variables.

- **x**: fa, ma, sa -> früh-, mittel-, spätadult; fm, mm, sm -> früh-, mittel-, spätmatur; s -> senil
- **a**
- **Dx**
- **dx**
- **lx**
- **qx**
- **Lx**
- **Tx**
- **ex**

For further information about the values see the documentation of [life.table](#).

## Details

This lifetable is compiled from a medieval grave collection from Schleswig (11th-13th century). More information can be found in *Grupe 1997*.
